A project

Idea of this section is to go through an example project end-to-end

• presenting concepts while applying them

Steps:

- frame your problem
- select a performance measure
- get the data
- descriptive statistics \rightarrow discover and visualize the data to gain insights
- data pre-processing \rightarrow prepare the data for ML algos
- model selection, model training
- model fine-tuning
- solution presentation
- launch, monitor, maintain your newly deployed system

In some (many!) aspects of most parts, allow me shortcuts and simplification..

• I hope the teaching value of this exercise stays intact..

INFN Machine Learning course

The project

Build a model of housing prices in California using the California census data.

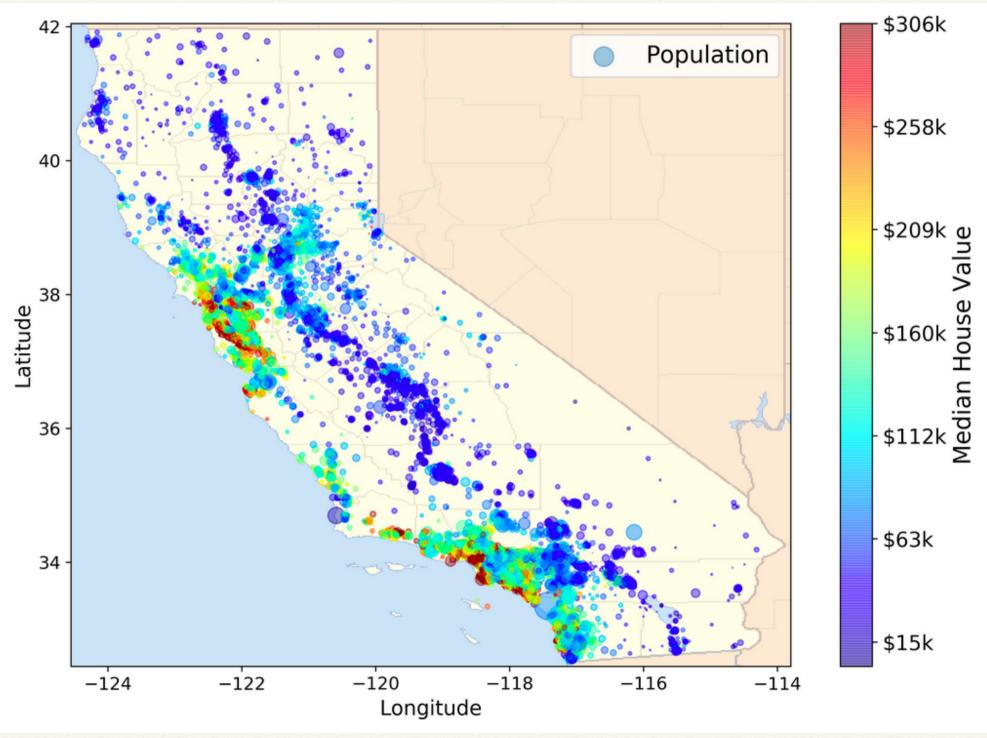

Pretend to be a recently-hired data scientist in a real estate company in California, and you are asked to predict the price of a house given various parameters, having at your disposal the **California Housing Prices dataset**:

• from the StatLib repository: R. Kelley Pace and Ronald Barry, "Sparse Spatial Autoregressions," Statistics & Probability Letters 33, no. 3 (1997): 291–297

From this dataset, you know:

- population, median income, median housing price, much more.. for each block group (of 600-3000 people) - called "districts"
 - caveats: not updated (data from the 90s) and minor mods (added a categorical attribute, removed a few features for teaching purposes)

Your model should learn from this data and be able to predict the median housing price in any district, given all the other metrics

Frame the problem / ask questions - step 1

Building a model is not the goal. Ask for the goal(s).

Good questions are:

- "what is my model being used for, eventually?"
 - this tells you how you concretely organise the approach to the problem, what algorithms you will select, what performance measure you will use to evaluate your model, how much effort you should invest in each (sub-)part of the work
- "what the current status of study of this problem is (if any)?"
 - * this gives you a reference performance, as well as insights on how to solve the problem
- "what the expected full data pipeline which my solution will insert in?"
 - Data pipeline as a sequence of data processing components. Very common in ML. Async and selfcontained components, data store as the only interface, different teams on different components, tactics for broken components, monitoring, etc

Frame the problem / make assumptions - step 2

Is it Supervised, Unsupervised, or Reinforcement Learning? Is it a classification task or a regression task? Should you use batch learning or online learning techniques?

(... think ...)

it is a **supervised** learning task..

• you are given labeled training examples: each instance comes with the expected output, i.e. the district's median housing price

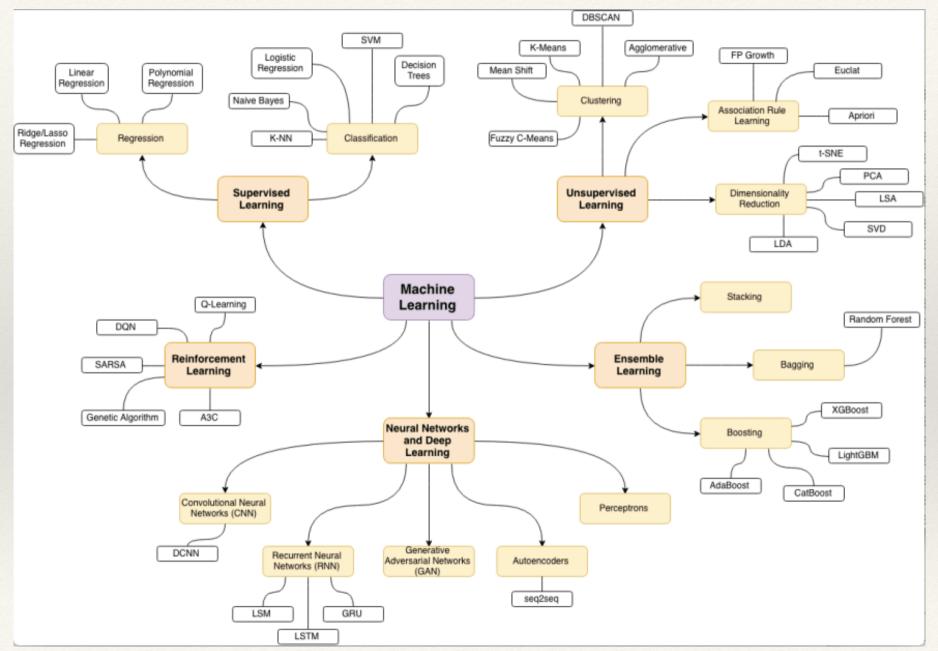

it is a **univariate regression** task..

• you are asked to predict a value, and a single one per district

Batch learning techniques should work just fine..

 data is small enough to fit in memory, there is no continuous flow of data coming in the system, there is no particular need to adjust to changing data rapidly

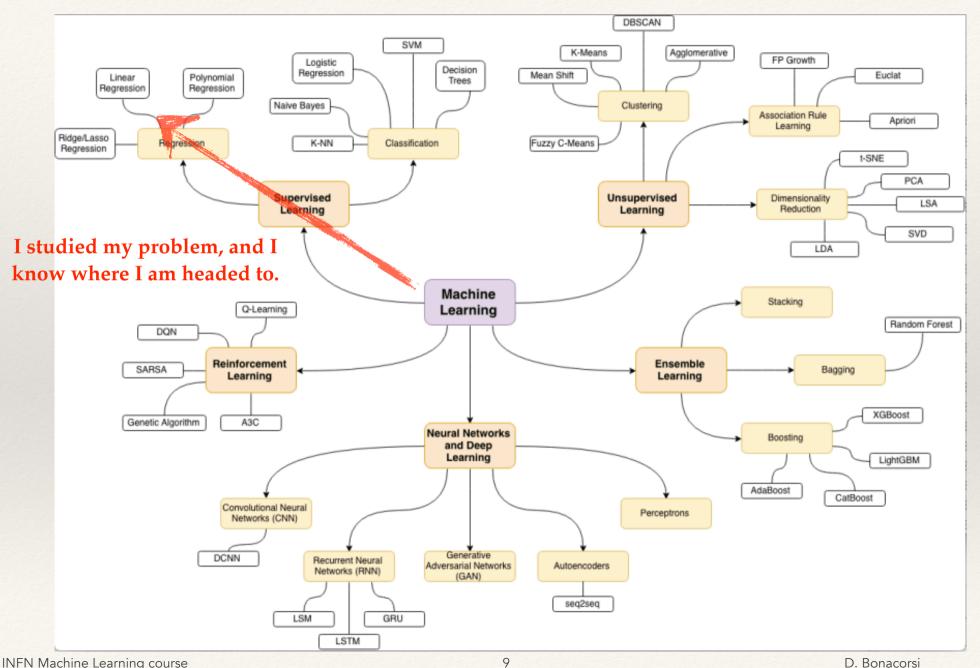

"I have the feeling I did nothing so far?"

INFN Machine Learning course

8

"Phew, I was wrong!"

INFN Machine Learning course

9

Frame the problem / check assumptions - step 3

After knowing the full pipeline (out of your own work)e.. recheck your assumptions.

So far: Supervised. Univariate regression. Batch learning

• "is any other components in the overall work pipeline making my assumptions unnecessary or tactically wrong?"

Suppose your value predictions are going to be clustered into coarse-grain categories (e.g. just "cheap", "medium", "expensive"). Then, getting the price perfectly right is not important at all, you just need to get the category right, and your task should have been framed as a **classification task** instead!

Notation

m	# of instances , i.e. examples in the training set
x	"input" variables, or " features " (a vector)
у	"output" variable, or " label " (aka "target")
(x ⁽ⁱ⁾ , y ⁽ⁱ⁾)	the single i th training example (i th row)

Select a performance measure

A typical performance measure for regression problems is the Root Mean Square Error (RMSE)

• it gives an idea of how much error the system typically makes in its predictions: the smaller it is the better

Or the Mean Absolute Error (MAE) - aka Average Absolute Deviation

RMSE
$$(\mathbf{X}, h) = \sqrt{\frac{1}{m} \sum_{i=1}^{m} (h(\mathbf{x}^{(i)}) - y^{(i)})^2}$$
 MAE $(\mathbf{X}, h) = \frac{1}{m} \sum_{i=1}^{m} |h(\mathbf{x}^{(i)}) - y^{(i)}|$

 $h \rightarrow my$ hypothesis for y

Both are ways to measure the distance between two vectors (predictions and labels). Various distance measures, or norms, are possible:

- RMSE \rightarrow root of sum of squares \rightarrow Euclidean norm, or ℓ_2 norm, often noted || ||₂
- MAE \rightarrow sum of absolutes \rightarrow Manhattan norm, or ℓ_1 norm, often noted || ||_1

In general:

- ℓ_k norm of a vector **v** containing n elements: $||\mathbf{v}||_k = (|v_0|^k + |v_1|^k + ... + |v_n|^k)^{1/k}$
- ℓ_0 gives the # non-zero elements; ℓ_{∞} gives the max absolute value in the vector

Which one?

• The higher the norm index, the more it focuses on large values and neglects small ones. This is why RMSE is more sensitive to outliers than the MAE (if you have outliers, use MAE; when outliers are exponentially rare (like in a bell-shaped curve), RMSE performs very well and is generally preferred

Inspect the data

Each row represents one district. There are 10 attributes (columns):

 longitude, latitude, housing_median_age, total_rooms, total_bedrooms, population, households, median_income, median_house_value, and ocean_proximity

The pandas info() method is useful to get a quick description of the data

• total number of rows and columns, each attribute's type, # non-null values

housing.info()

C <class 'pandas.gore.frame.BataFrame'> RangeIndex: 20640 entries, 0 to 20639 Data columns (total 10 columns):

		····· / ·		
longitude	20640	non-null	float64	
latitude	20640	non-null	float64	
housing_median_age	20640	non-null	float64	
total_rooms		non-null		
total_bedrooms	20433	non-null	float64	
population	20640	non-null	float64	
households	20640	non-null	float64	
median_income	20640	non-null	float64	
median_house_value	20640	non-null	float64	
ocean_proximity	20640	non-null	object	
dtypes: float64(9),	object(1	L)		
memory usage: 1.6+ M	В			

20,640 instances in the dataset

total_bedrooms attribute has only 20,433 non-null values, meaning that 207 districts are missing this feature

Inspect the data

All attributes numerical, except ocean_proximity. Its type is object, so it could hold any kind of py object, but you loaded from a CSV file so you know that it must be a text attribute. Probably categorical: use value_counts()

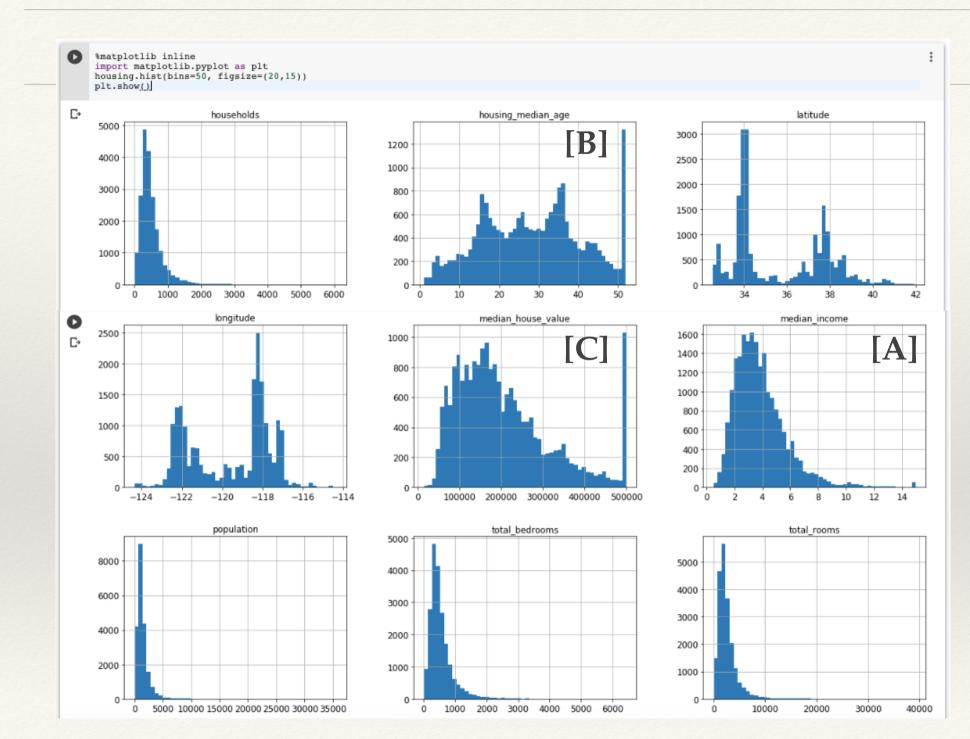

housing["ocean_proximity"].value_cou	
<pre> <1H OCEAN 9136 INLAND 6551 NEAR OCEAN 2658 NEAR BAY 2290 ISLAND 5 Name: ocean proximity, dtype: int6</pre>	4

The describe() method shows a summary of the numerical attributes

null values are ignored

:

Inspect the data

Notice a few things in these histograms:

- [A] attribute not expressed in the **expected units** (USD). Ask who gave you the data.. it is in tens of thousands of USD
- **[B] [C]** were **capped**. Note you have a label here. It could be a problem. Your ML algo may learn that prices never go beyond that limit, which is wrong. Check if you need precise predictions also in those ranges.. If yes, either you collect proper labels for the districts whose labels were capped, or you remove those examples from the training set (and the test set)
- The attributes (e.g. [A] [C]) have very different scales → feature scaling (later)
- Many histograms are skewed: this may make it a bit harder for some ML algos to detect patterns → transform attributes to get symmetric distributions

Some steps have been done towards a better understanding of the kind of data you are dealing with.

. . .

Create a test set

Take a subset of your data and put it aside.

Why? Because your brain is an amazing pattern detection system and you should avoid it to trick you!

 i.e. your brain is highly prone to overfitting. Looking at the test set, you might see some patterns and be biassed towards some ML model. Then, when you estimate the generalisation error using the test set, your estimate will be too optimistic and you will launch a system that will eventually perform on new data much worse than expected → "data snooping bias"

0	from sklearn.model_selection import train_test_split	:
	<pre>train_set, test_set = train_test_split(housing, test_size=0.2, random_state=42)</pre>	

>90% of ML practitioners do this.. but..

Sampling: purely random vs stratified

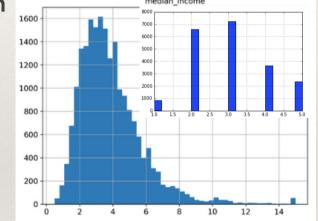

Purely random sampling works OK only if the dataset is large enough. If not, you risk to introduce a significant sampling bias

Best is to use **stratified sampling**

 as the population is divided into homogeneous subgroups called strata, sample the right number of instances from each stratum to guarantee that the test set you build is representative of the overall population

E.g. if you are told that median income is an important attribute to predict house prices in a district, make sure you represent all categories of salary in your test set

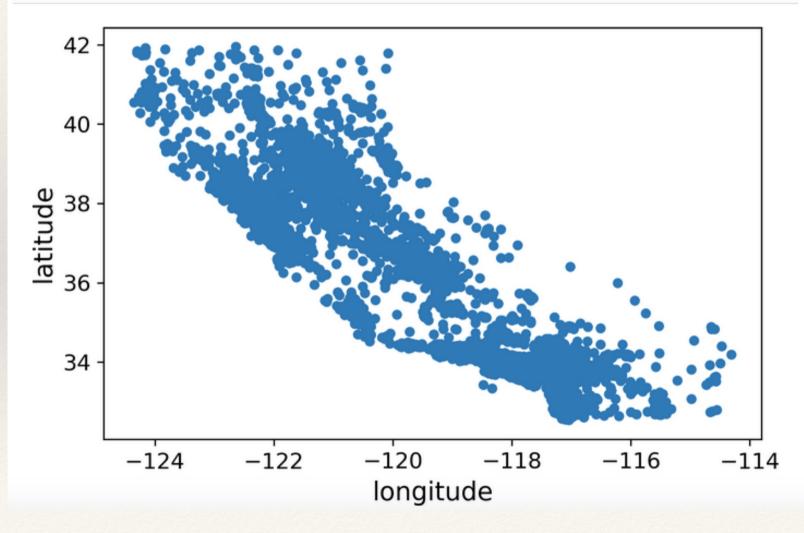

- create e.g. 5 categories, assign examples to each
- then, use the sklearn's StratifiedShuffleSplit class
- compare the income category proportions in the overall dataset, in the test set generated with stratified sampling, and in a test set generated using purely random sampling

		<u>e</u>			<u></u>
	Overall	Stratified	Random	Rand. %error	Strat. %error
1	0.039826	0.039729	0.040213	0.973236	-0.243309
2	0.318847	0.318798	0.324370	1.732260	-0.015195
3	0.350581	0.350533	0.358527	2.266446	-0.013820
4	0.176308	0.176357	0.167393	-5.056334	0.027480
5	0.114438	0.114583	0.109496	-4.318374	0.127011

For geolocated data, this often gives useful insights.

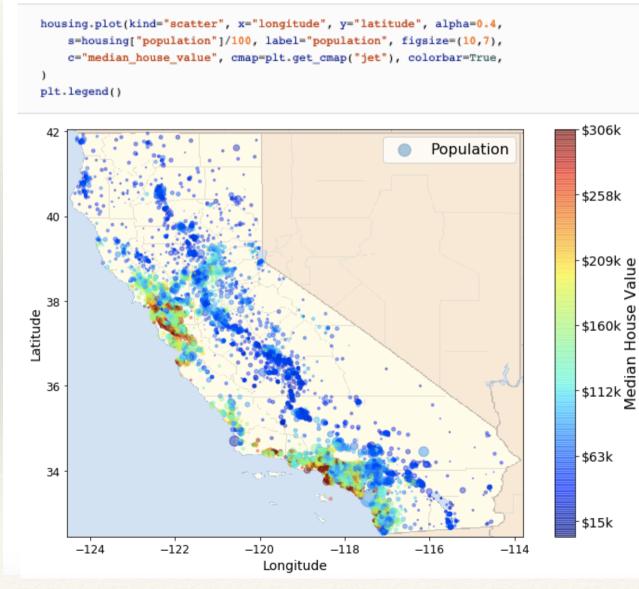

housing.plot(kind="scatter", x="longitude", y="latitude")

Use matplotlib features to highlight high density patterns.

Display population by circles' size and house price by colors on a heatmap.

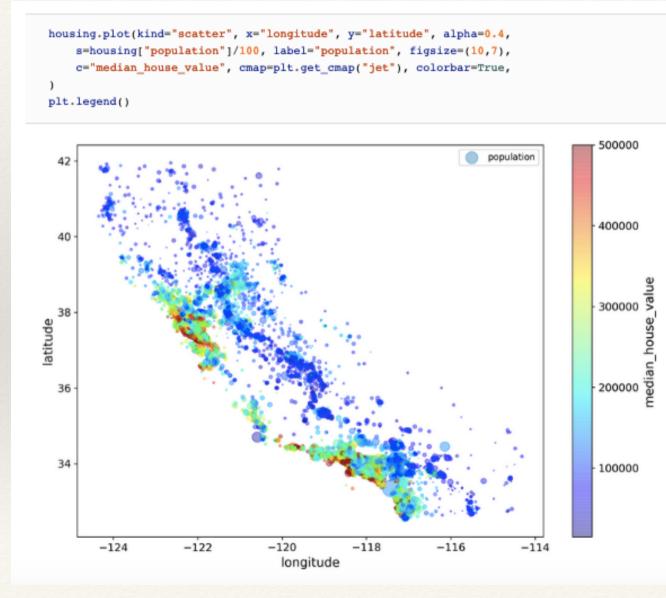

Housing prices are very much related to location (e.g. close to the ocean) and to the population density.

Use a clustering algo to detect the main clusters?

Careful about ocean proximity attribute: perhaps useful but works different North vs South, so not a simple rule..

Display population by circles' size and house price by colors on a heatmap.

Use a clustering algo to detect the main clusters?

Careful about ocean proximity attribute: perhaps useful but works different North vs South, so not a simple rule..

Looking for **correlations** (numerically)

Dataset not huge \rightarrow compute the **standard correlation coefficient** (aka **Pearson's r**) between every pair of attributes

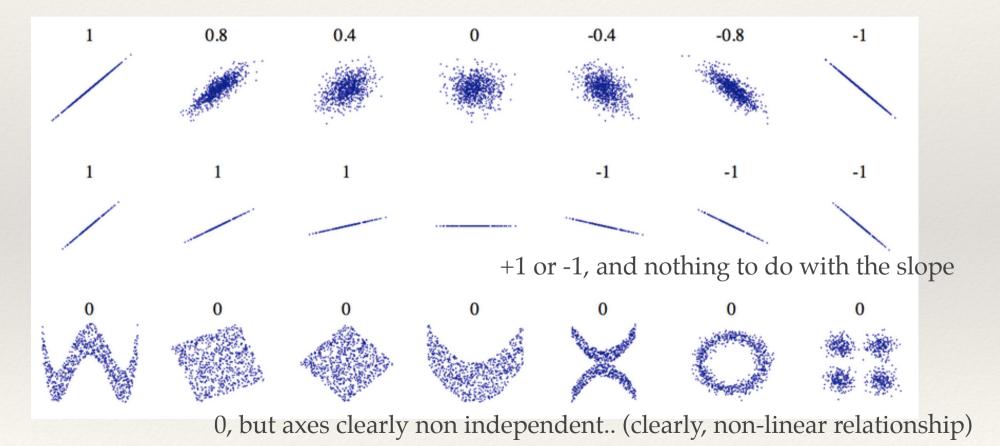

• e.g. check how much each attribute correlates with the median house value

```
[53] corr matrix = housing.corr()
     corr matrix["median house value"].sort values(ascending=False)
    median house value
                          1.000000
 ⊡
    median income
                          0.687160
    total rooms
                          0.135097
                                                  Median house value tends to go up
    housing median age
                          0.114110
    households
                          0.064506
                                                   when the median income goes up
    total bedrooms
                          0.047689
    population
                         -0.026920
    longitude
                         -0.047432
                                                Small negative correlation between the
    latitude
                         -0.142724
    Name: median_house_value, dtype: float64
                                               latitude and the median house value (i.e.
                                               prices have a slight tendency to go down
                                                          when you go north)
```

Standard correlation coefficient of various datasets

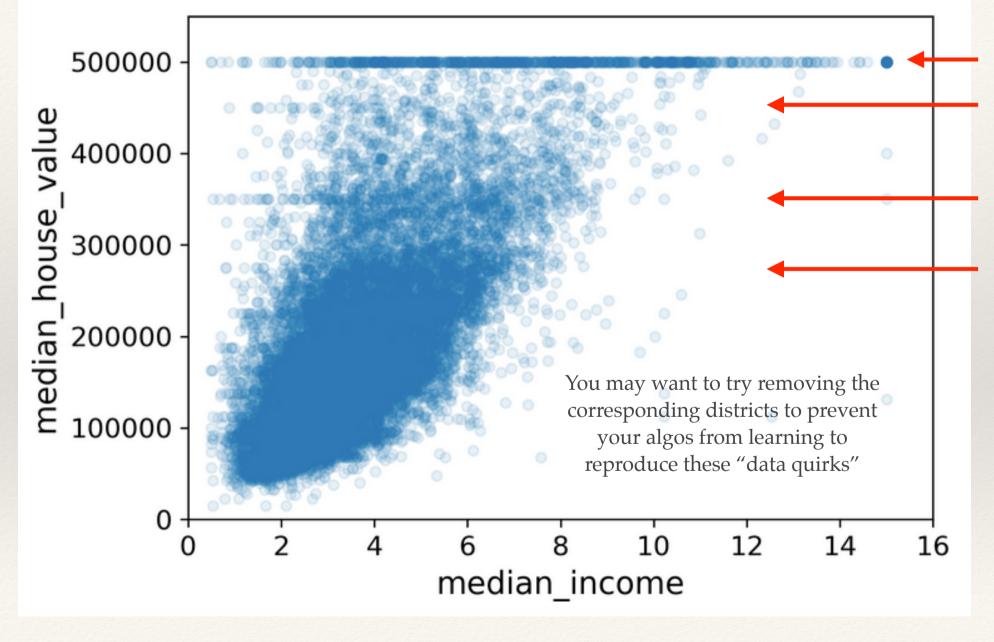

The correlation coefficient only measures linear correlations

• it may completely miss out on nonlinear relationships (e.g., "if x is close to zero then y generally goes up").

Looking for **correlations** (visually)

Explore attribute combinations

housing["rooms_per_household"] = housing["total_rooms"]/housing["households"]
housing["bedrooms_per_room"] = housing["total_bedrooms"]/housing["total_rooms"]
housing["population_per_household"]=housing["population"]/housing["households"]

median_house_value	1.000000	
median_income	0.687170	
total_rooms	0.135231	
housing_median_age	0.114220	
households	0.064702	
total_bedrooms	0.047865

	bedrooms_per_room	-0.259984
	Name: median_house_value,	dtype: float64

Create and add more meaningful attributes. And re-check correlation matrix.

Not bad:

- one of the <u>new</u> variables (bedrooms per room) is more anti-correlated to median house value than other old variable like the total number of rooms or bedrooms. Apparently houses with a lower bedroom/room ratio tend to be more expensive.
- The number of rooms per household is also more informative than the total number of rooms in a district—obviously the larger the houses, the more expensive they are.

Data preparation for ML algos: data cleaning

Deal with **missing features**

• remember total_bedrooms, that had missing entries?

3 options:

- Get rid of the corresponding districts \rightarrow drop rows
- Get rid of the whole attribute \rightarrow drop a single column
- Set the values to some value (zero, the mean, the median, etc.) → save it as you will need it for the test set too, or if/when the systems goes live to replace new missing values

Data prep for ML: Handling Text and Categorical Attributes

Need to convert categories from text to numbers.

```
from sklearn.preprocessing import OrdinalEncoder
                                                                    This representation has the issue
ordinal encoder = OrdinalEncoder()
housing cat encoded = ordinal encoder.fit transform(housing cat)
                                                                    that ML algos will assume that 2
housing cat encoded[:10]
                                                                     nearby values are more similar
array([[0.],
       [0.],
                                                                          than 2 distant values.
       [4.],
       [1.],

      [0., 1., 0., 0., 0.],
      [1., 0., 0., 0., 0.],
      [0., 0., 0., 1., 0.]])
```

A common solution is to create one binary attribute per category. This is called **one-hot encoding**, because only one attribute will be equal to 1 (hot), while the others will be 0 (cold).

Data preparation for ML algos: Feature scaling

ML algos don't perform well when the input numerical attributes have very different scales

There are 2 common ways to get all attributes to have the same scale:

• **min-max scaling** (aka **normalisation**): values are shifted and rescaled so that they end up all ranging from 0 to 1 (or any other similar range)

* useful e.g. for NN

• **standardisation**: it subtracts the mean value (so standardised values always have a zero mean), and then it divides by the standard deviation so that the resulting distribution has unit variance

much less affected by outliers w.r.t. normalisation

They can be used altogether.

Data preparation for ML algos: Transformation pipelines

Many data transformation steps that need to be executed in sequence and in the right order: sklearn provides the **Pipeline** class to help with such sequences of transformations.

```
from sklearn.pipeline import Pipeline
from sklearn.preprocessing import StandardScaler
num_pipeline = Pipeline([
        ('imputer', SimpleImputer(strategy="median")),
        ('attribs_adder', CombinedAttributesAdder()),
        ('std_scaler', StandardScaler()),
    ])
housing num tr = num pipeline.fit transform(housing num)
```

Select and Train a Model

Here we are!

- I framed the problem
- I got the data and explored it
- I sampled a training set and a test set
- I wrote transformation pipelines to clean up and prepare data for ML

Now, data is ready, and next is to select and train a ML model

• start simple: a linear model

Did this give you a feeling as of how much time to spend on e.g. input data preprocessing w.r.t model selection?

Select and Train a Model

How is the model working? Let's try some predictions!

```
>>> some_data = housing.iloc[:5]
>>> some_labels = housing_labels.iloc[:5]
>>> some_data_prepared = full_pipeline.transform(some_data)
>>> print("Predictions:", lin_reg.predict(some_data_prepared))
Predictions: [ 210644.6045 317768.8069 210956.4333 59218.9888 189747.5584]
>>> print("Labels:", list(some_labels))
Labels: [286600.0, 340600.0, 196900.0, 46300.0, 254500.0]
```

<u>It works</u>, although the predictions are not exactly accurate (e.g. the first is off by close to 40%!). Measure the RSME on the whole training set:

```
>>> from sklearn.metrics import mean_squared_error
>>> housing_predictions = lin_reg.predict(housing_prepared)
>>> lin_mse = mean_squared_error(housing_labels, housing_predictions)
>>> lin_rmse = np.sqrt(lin_mse)
>>> lin_rmse
68628.19819848922 well.. I get this, as a typical prediction error, when median
housing values range between $120,000 and $265,000..
```

Clearly not a great score (underfitting) but it is a start! (and it was quick!)

INFN Machine Learning course

Select and Train a Model

This point is one of the most tricky you will encounter in project on real-world datasets

- i.e. "I need to make a choice. What do I try next?"
- data science is general is done via experienced trials.. no recipes written in stones on most aspects.. And all may largely be dependant on your dataset..

Common practices help you, though. This case:

- **symptoms of underfitting**: this is already A LOT to drive your next choice!
- main ways to fix underfitting are:
 - select a more powerful model
 - feed the training algorithm with better features
 - * reduce the constraints on the model

What would you choose?

Select and Train a Model

This point, and not others, is one of the most difficult you will encounter in project on real-world datasets

- i.e. "I need to make a choice. What do I try next?"
- data science is general is done via experienced trials.. no recipes written in stones anywhere! And all largely dependant on your dataset!

Common practices help you, though. This case:

- symptoms of underfitting: this is already A LOT to drive your next hoice!
- main ways to fix underfitting are:
 - Select a more powerful model → you can try, and much cheaper
- * feed the training algorithm with better features \rightarrow you can try, but expensive..
- * reduce the constraints on the model \rightarrow non regularized, so this is ruled out

Select and Train a Model

Try a decision tree.

• Because it is a powerful model, capable of finding complex nonlinear relationships in the data

from sklearn.tree import DecisionTreeRegressor

```
tree_reg = DecisionTreeRegressor()
tree_reg.fit(housing_prepared, housing_labels)
```

Now that the model is trained, evaluate it on the training set:

```
>>> housing_predictions = tree_reg.predict(housing_prepared)
>>> tree_mse = mean_squared_error(housing_labels, housing_predictions)
>>> tree_rmse = np.sqrt(tree_mse)
>>> tree_rmse
0.0
```

Wait, what!? No prediction error AT ALL!? Is it PERFECT!?

• much more likely that the model has badly overfit the data.. I need to be sure though.. How?

I can't touch the **test set** (until I am ready to launch a model I am decently confident about). So I need to **use a sub-part of the training set for training, and a sub-part for..** <u>model validation</u>

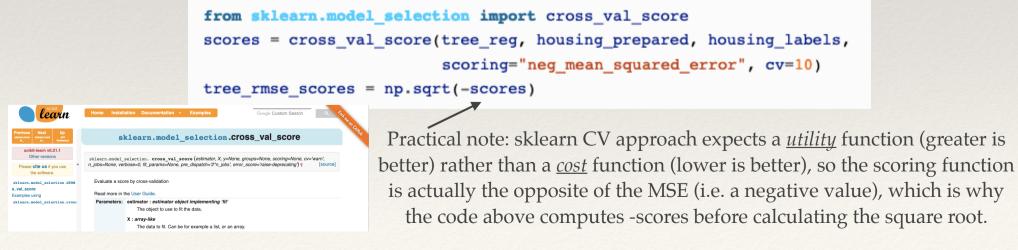

Model Evaluation w/ k-fold Cross-Validation

You can (statically):

• split the original training set into train and validation sets, train your model on the (smaller) training sub-set and evaluate it against the validation sub-set

Or (more dynamically)...

- randomly split the training set into k distinct subsets called "folds"
 - * or think of strata if you think it is the case..
- permute and pick k-1 fields for training and evaluate on the remaining 1, i.e. train and evaluate your model **k times**
- the result is an array containing the **k evaluation scores** (you will average..)

Model Evaluation w/ k-fold Cross-Validation

Lets look at results:

SSS def display accord (accord).
<pre>>>> def display_scores(scores):</pre>
print("Scores:", scores)
<pre> print("Mean:", scores.mean())</pre>
<pre> print("Standard deviation:", scores.std())</pre>
•••
<pre>>>> display_scores(tree_rmse_scores)</pre>
Scores: [70194.33680785 66855.16363941 72432.58244769 70758.73896782
71115.88230639 75585.14172901 70262.86139133 70273.6325285
75366.87952553 71231.65726027]
Mean: 71407.68766037929
Standard deviation: 2439.4345041191004

• the good: I have k models, so this techniques gives me a standard deviation too

* it came at the cost of multiple trainings, you cannot afford it always..

- the bad: the score with a more complex model is worse than that with a simpler one.. no progress?
 - wait we are comparing LinearRegression w/o CV (RMSE 68628) with DecisionTreeRegressor w CV (RMSE 71407). For a fair comparison, o be sure, run CV also for LinearRegression.. you get 69052 with a std deviation of 2731..

Not getting better: it is comparably bad, even with a more complex model and with proper CV..

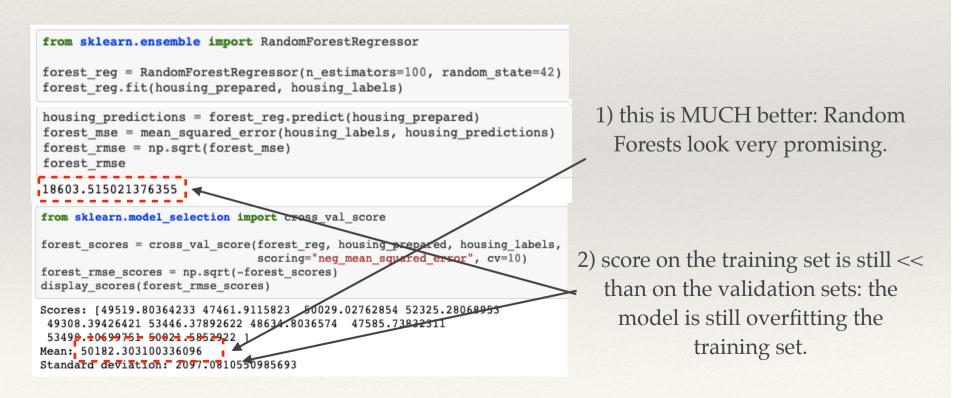

Observation:

Model Evaluation: cont'd

(... the karma: "I need to make a choice. What do I try next?" ...)

Try one more model: Random Forest.

- it is an Ensemble Learning technique: build a model on top of many other models
 - it works by training many Decision Trees on random subsets of the features, then averaging out their predictions

Model Evaluation w/ k-fold Cross-Validation

Possible solutions:

- simplify the model
- constrain it (i.e. regularize it)
- get a lot more training data

What would you choose?

Towards fine-tuning..

Possible solutions:

- simplify the model → we just moved to a more complex.. perhaps try others?
- constrain it (i.e. regularize it) → this is **fine tuning of hypermeters**
- get a lot more training data → this (alone) might work only in some cases..

Towards fine-tuning..

Possible solutions:

- simplify the model → we just moved to a more complex.. perhaps try others?
- constrain it (i.e. regularize it) → this is fine tuning of hypermeters
- get a lot more training data → this (alone) might work only in some cases..

Try out many other models from various categories of ML algos

- e.g. Support Vector Machines with different kernels
- e.g. possibly a Neural Network..

w/o spending too much time (yet) tweaking the hyperparameters

The goal is to **shortlist a few (5ish?) promising models**, and continue the work in parallel with them altogether

• yes, the work is self-organising in various branches.. to be constantly compared..

Hyper-parameters and model fine-tuning

Let's assume that I have now a shortlist of (few) promising models.

I need to fine-tune them.

One way to do that would be to fiddle with the hyperparameters manually, until you find a great combination of their values that "magically" works

• this would be very tedious and time-consuming..

There are various ways to automatically do so:

- GridSearch
- Randomised Search
- Ensemble Methods

Grid Search

Grid Search does the **search** (via CV) of the best parameters across all permutations in the parameters' **grid**

 all you need to do is tell which hyper-parameters you want it to experiment with, and what values to try out

Note: do not worry about what these params mean: these are for RandomForest Regressor, others do have different ones..

Focus on the fact that this GridSearch launch 90 training passes in one go!

Grid Search

```
cvres = grid_search.cv_results_
for mean_score, params in zip(cvres["mean_test_score"], cvres["params"]):
    print(np.sqrt(-mean_score), params)

63669.05791727153 {'max_features': 2, 'n_estimators': 3}
55627.16171305252 {'max_features': 2, 'n_estimators': 10}
53384.57867637289 {'max_features': 2, 'n_estimators': 30}
60965.99185930139 {'max_features': 4, 'n_estimators': 3}
52740.98248528835 {'max_features': 4, 'n_estimators': 10}
50377.344409590376 {'max_features': 4, 'n_estimators': 30}
58663.84733372485 {'max_features': 6, 'n_estimators': 3}
52006.15355973719 {'max_features': 6, 'n_estimators': 10}
50146.465964159885 {'max_features': 6, 'n_estimators': 30}
```

62895.088889905004 {'bootstrap': False, 'max_features': 2, 'n_estimators': 3} 54658.14484390074 {'bootstrap': False, 'max_features': 2, 'n_estimators': 10} 59470.399594730654 {'bootstrap': False, 'max_features': 3, 'n_estimators': 3} 52725.01091081235 {'bootstrap': False, 'max_features': 3, 'n_estimators': 10} 57490.612956065226 {'bootstrap': False, 'max_features': 4, 'n_estimators': 3} 51009.51445842374 {'bootstrap': False, 'max_features': 4, 'n_estimators': 10} Let's look at the score of each hyper parameter combination tested during the grid search

grid_search.best_params_
{'max_features': 8, 'n_estimators': 30}
grid_search.best_estimator_

57869.25504027614 {'max_features': 8, 'n_estimators': 3} 51711.09443660957 {'max_features': 8, 'n_estimators': 10} 49682.25345942335 {'max_features': 8, 'n_estimators': 30}

The RMSE score for this combination is 49,682 (code not shown): slightly better than the score you got earlier using the default hyperparameter values (it was 50,182).

Some fine tuning worked!

Would you stop here!?

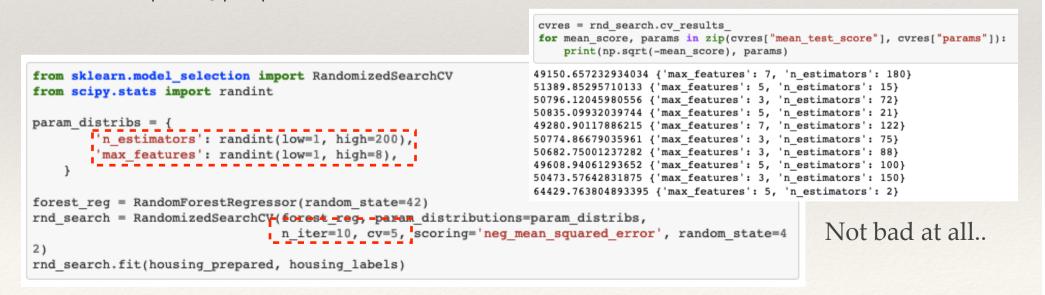

• Hint: the chosen parameters happens to be the maximum values that were evaluated..

Randomized Search

Grid Search is fine when exploring relatively few combinations. Move to **Randomized Search** if you want a larger hyperparameter search space

Instead of trying out all possible combinations, it evaluates a **given number of random combinations by selecting a random value for each hyperparameter at every iteration**.

 if you let the randomised search run for, say, 1000 iterations, this approach will explore 1,000 different values for <u>each</u> hyperparameter (instead of just a few values per hyperparameter as with GridSearch)

Ensemble Methods

This is another way to fine-tune your system: try to **combine the models that perform best**, as the group (or "**ensemble**") will often perform better than the best individual model

- we saw this already: RandomForest performed better than the individual DecisionTrees it relied on
- especially good if the individual models make very different types of prediction errors

Analyze the best models and their prediction errors

Crucial to understand why a model is working better than others

• "who drove this model to the point it performs the best?"

Feature importance: e.g. RandomForestRegressor can indicate the relative importance of each attribute for making accurate predictions

You may want to try dropping some of the less useful features

(e.g. apparently only one ocean_proximity category is really useful, so you could drop the others)

```
>>> extra attribs = ["rooms per hhold", "pop per hhold", "bedrooms per room"]
>>> cat encoder = full pipeline.named transformers ["cat"]
>>> cat one hot attribs = list(cat encoder.categories [0])
>>> attributes = num attribs + extra attribs + cat one hot attribs
>>> sorted(zip(feature_importances, attributes), reverse=True)
(0.3661589806181342, 'median income'),
 (0.1647809935615905, 'INLAND'),
 (0.10879295677551573, 'pop per hhold'),
 (0.07334423551601242, 'longitude'),
 (0.0629090704826203, 'latitude'),
 (0.05641917918195401, 'rooms per hhold'),
 (0.05335107734767581, 'bedrooms per room'),
 (0.041143798478729635, 'housing median age'),
 (0.014874280890402767, 'population'),
 (0.014672685420543237, 'total rooms'),
 (0.014257599323407807, 'households'),
 (0.014106483453584102, 'total bedrooms')
 (0.010311488326303787, '<1H OCEAN')
 (0.002856474637320158, 'NEAR OCEAN'),
(0.00196041559947807, 'NEAR BAY'),
(6.028038672736599e-05, 'ISLAND')]
```

But do more!

• add extra features or, on the contrary, get rid of uninformative ones, cleaning up outliers, etc

Evaluate Your System on the Test Set

OK. You eventually have a system that performs sufficiently well. Now is the time to **evaluate the final model on the test set**.

Easy, and nothing technical different wrt what we did already

- get features and labels from your test set, now
- run your full pipeline to transform the data (transform(), not fit_transform() !)
- evaluate the final model on the test set

```
final_model = grid_search.best_estimator_
X_test = strat_test_set.drop("median_house_value", axis=1)
y_test = strat_test_set["median_house_value"].copy()
X_test_prepared = full_pipeline.transform(X_test)
final_predictions = final_model.predict(X_test_prepared)
final_mse = mean_squared_error(y_test, final_predictions)
final_rmse = np.sqrt(final_mse)  # => evaluates to 47,730.2
```

Not bad. Communicate out:

You got an idea of features importances (median income as main predictor), you studied and excluded some features (e.g. some of the ocean vicinity ones), plenty of lesson learned (what worked and what not), you got a performance that can be compared with others

Depending on the case, (your boss will) **consider to switch the production system to this one**. (then, plenty of monitor, re-checks, etc..)
