Overview

Here I present recent results in the cluster counting efforts. The approach is now to determine what gains can be obtained with a given cluster-counting efficiency. We isolate one source of nearly irreducible inefficiency. Pion-kaon separation is examined for the first time.

All simulated data uses a single square 30mm cell, Helium:Isobutane 90 : 10, delta rays disabled.

Garfield Simulation Results

Shaping Function

$$s(t) = \frac{t}{\tau} e^{-\frac{t}{\tau}} \quad (1)$$

$$(f \star s)(i) = \sum_{j=-\infty}^{\infty} f(j)s(i-j) \quad (2)$$

This is all implemented using Python.

Data

Shaping Time Constant

A shaping time constant of around 4 nanoseconds with some random noise converts the ideal Garfield results into something that looks like our data. The time constant is determined by the choice of electronics (shaping amplifier) but also by the electrical properties of the chamber. Note that the correct scaling factor for the shaping function is not well-determined, so though clusters can be counted, values of voltage (and thus charge deposited) should be taken as qualitative.

Unfortunately a long time constant hinders our ability to count clusters.

Clusters With “Perfect” Signals

Number of Clusters 3, Threshold -7.00 mV

hNClusters3	
Entries	1001
Mean	28.59
RMS	5.824
Underflow	0
Overflow	0
Integral	1001

Clusters With $\tau = 2\text{ns}$

Number of Clusters 3, Threshold -7.00 mV

hNClusters3	
Entries	1001
Mean	20.82
RMS	4.758
Underflow	0
Overflow	0
Integral	1001

Clusters With $\tau = 4.5\text{ns}$ and 0.4mV Noise

Number of Clusters 3, Threshold -7.00 mV

hNClusters3	
Entries	1001
Mean	22.85
RMS	4.536
Underflow	0
Overflow	0
Integral	1001

Cluster Separation (“Perfect”)

Separation of 0th and 1th Clusters

hClustSep00	
Entries	1001
Mean	17.41
RMS	16.34
Underflow	0
Overflow	0
Integral	991

Cluster Counting Efficiency (from Giuseppe)

Pion-kaon separation

This is one area where cluster counting is hoped to dramatically improve results. The ionization behavior goes like $\frac{1}{m}$ whereas the actual tracks are nearly identical since they are relativistic. Even cluster counting which is not perfectly efficient could distinguish them.

We use 489 MeV momentum tracks, 4.5ns time constant for shaping, and 0.4mV RMS noise.

Deposited Charge (Red= π , Blue=K)

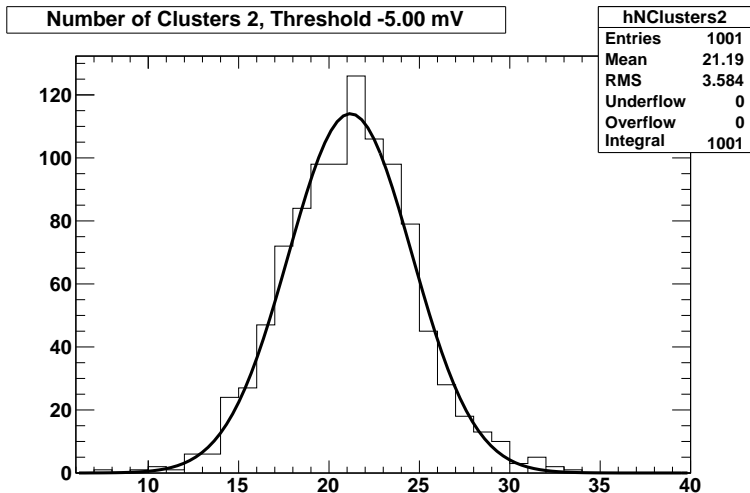

Total Charge (Baseline Corrected) (pC)

hTotalChargeBaselined	
Entries	1001
Mean	-1510
RMS	617.9
Underflow	86
Overflow	64
Integral	851

hTotalChargeBaselined	
Entries	1001
Mean	-987.2
RMS	471.9
Underflow	27
Overflow	76
Integral	898

Counted Clusters for Pions $\mu = 21.2, \sigma = 3.4$

Counted Clusters for Kaons $\mu = 27.7, \sigma = 3.9$

Counted Clusters (Red= π , Blue=K)

Number of Clusters 2, Threshold -5.00 mV

hNClusters2	
Entries	1001
Mean	27.11
RMS	3.96
Underflow	0
Overflow	0
Integral	1001

hNClusters2	
Entries	1001
Mean	20.69
RMS	3.584
Underflow	0
Overflow	0
Integral	1001

Conclusions

It is encouraging that we notice any difference between the pions and kaons in terms of clusters. Once the effect of the electronics is better understood, a quantitative estimate of the gains from cluster counting can be made.

Now that garfield simulated tracks can be analysed in a similar manner as real data from our drift tubes, we can use comparisons to take advantage of both methods.
