Bright events produced by lightning

“TGF events”

23 peculiar events collected from 2005 to 2017 (change in the SD trigger).

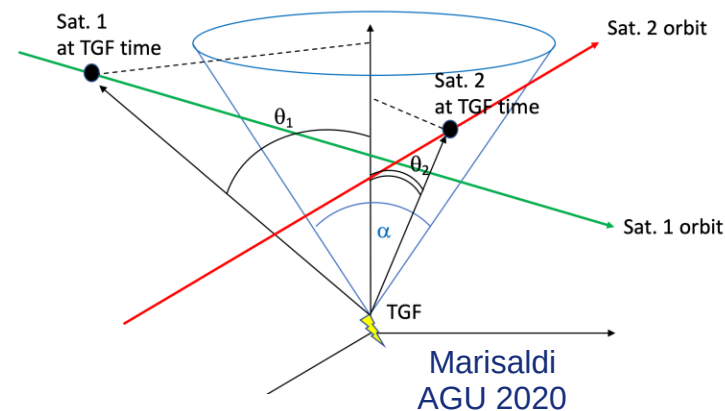

A dedicated trigger for TGF events was designed and installed.

Other work is necessary because the Pierre Auger Observatory was upgraded and the TGF algorithm needs to be optimized according to the new electronics.

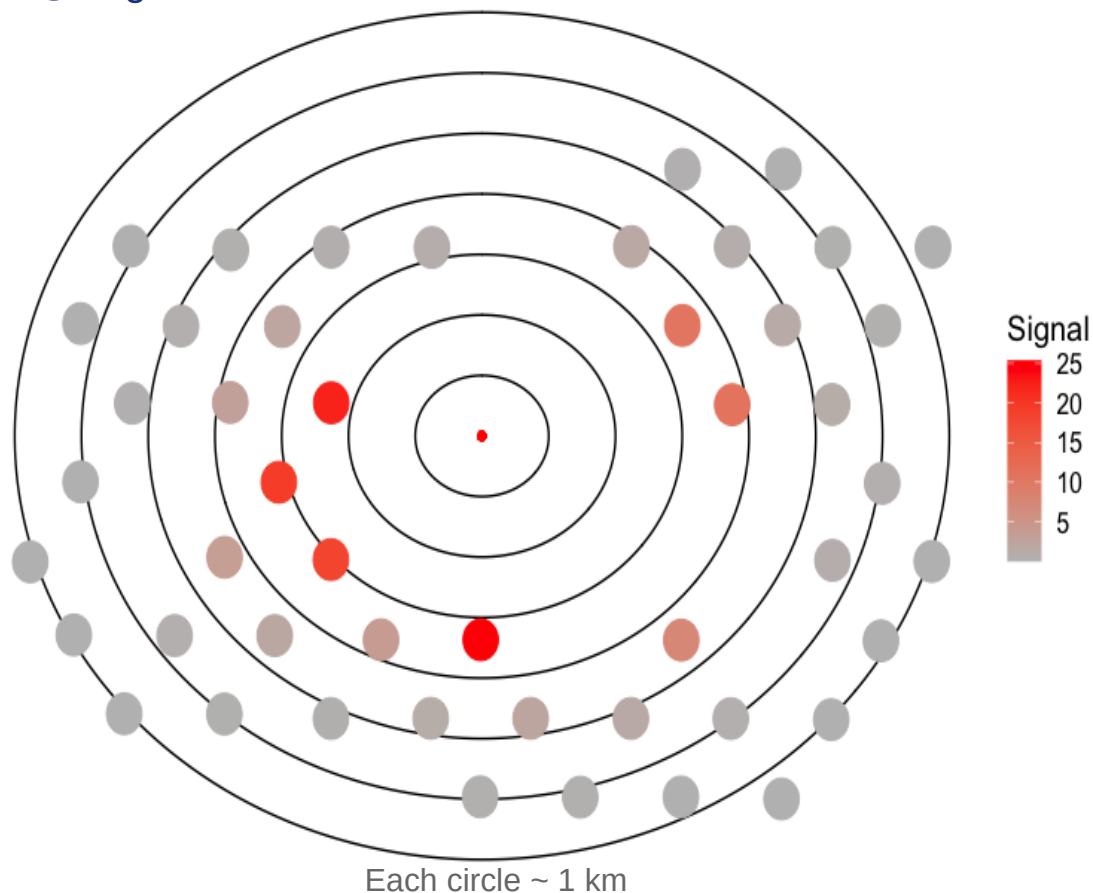

Advantages of a ground array

Greatest spatial
resolution
prior to Auger

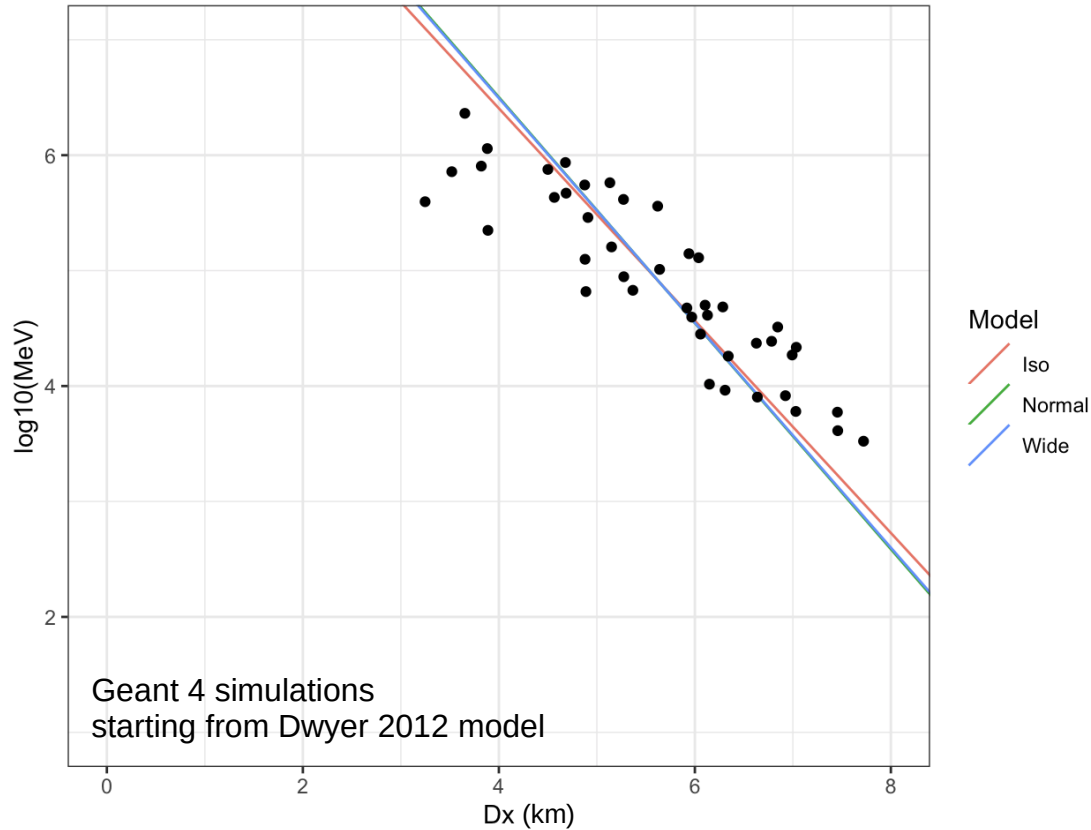

Advantages of a ground array

@Auger

- Reconstruction of the source position (few km above the ground)
- Sampling of the cone
→ study of the signal distribution
- Very detailed signal
→ Cherenkov detectors sensitive to gammas > 1 MeV
→ smooth time profile with 25 ns time resolution

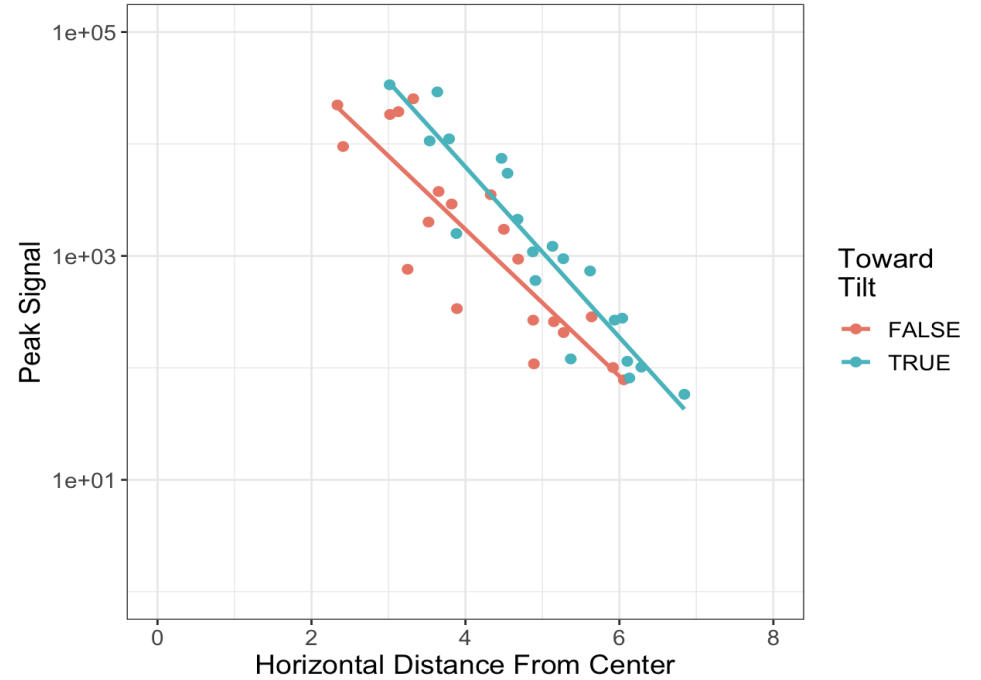

Comparison with standard TGF simulations

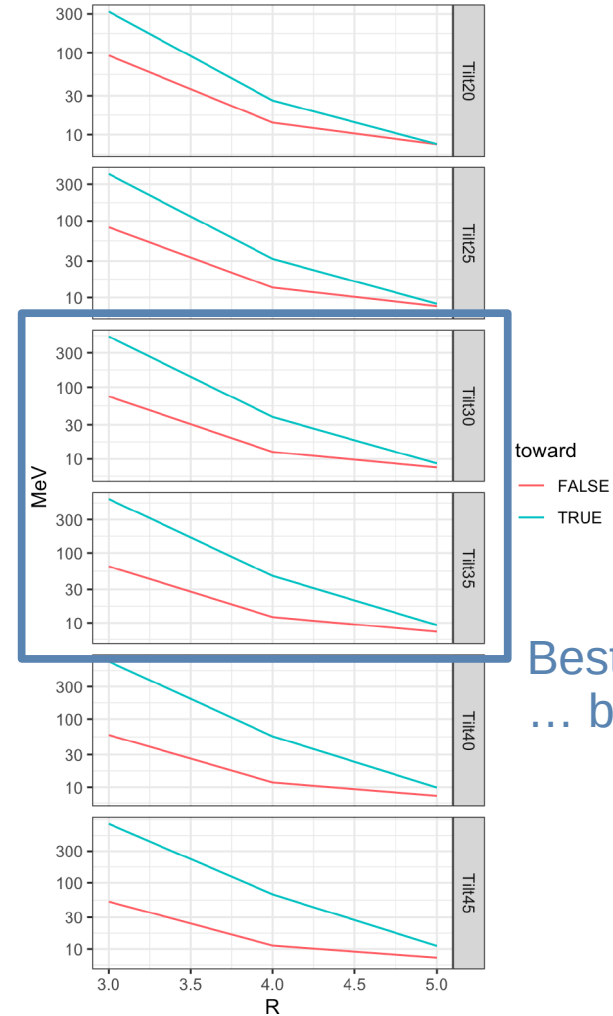

😊 Auger TGFs show a brightness similar to TGFs seen from space (10^{17} - 10^{18} photons)

😞 The slope is not very well reproduced by standard TGF models

Studying the signal distribution

Studying the signal distribution

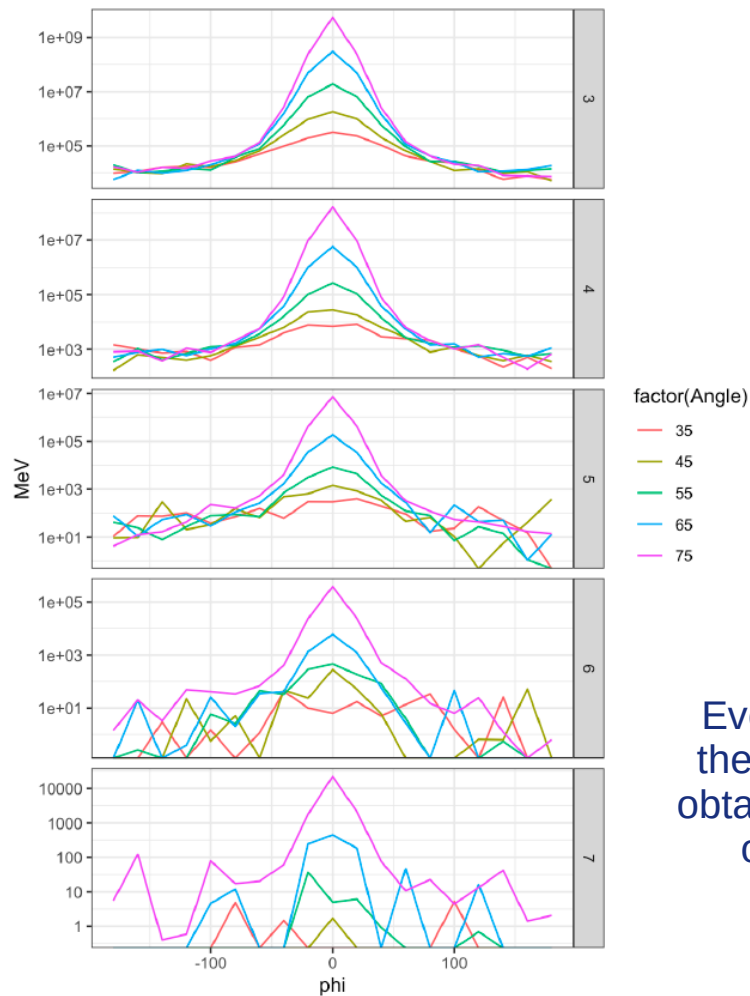

First evidence of an asymmetric TGF

Could it depend on the inclination?

First evidence of an asymmetric TGF

NO!
Even by increasing
the tilting angle, the
obtained signals have
only one peak.

Indication for different sources?

**Relativistic
Feedback**
assuming an
upward
positive leader

Overview

We present a visual review of some recent literature on terrestrial gamma-ray flashes (TGFs) and related phenomena (x-ray bursts from leader steps and gamma-ray glows). We place TGFs into three classes:

TYPE 1: TGFs produced at one end of an intracloud channel unconnected to ground (even if it will be eventually). These form one end of a continuum of behaviors, with x-ray bursts from stepped leaders at the other end.

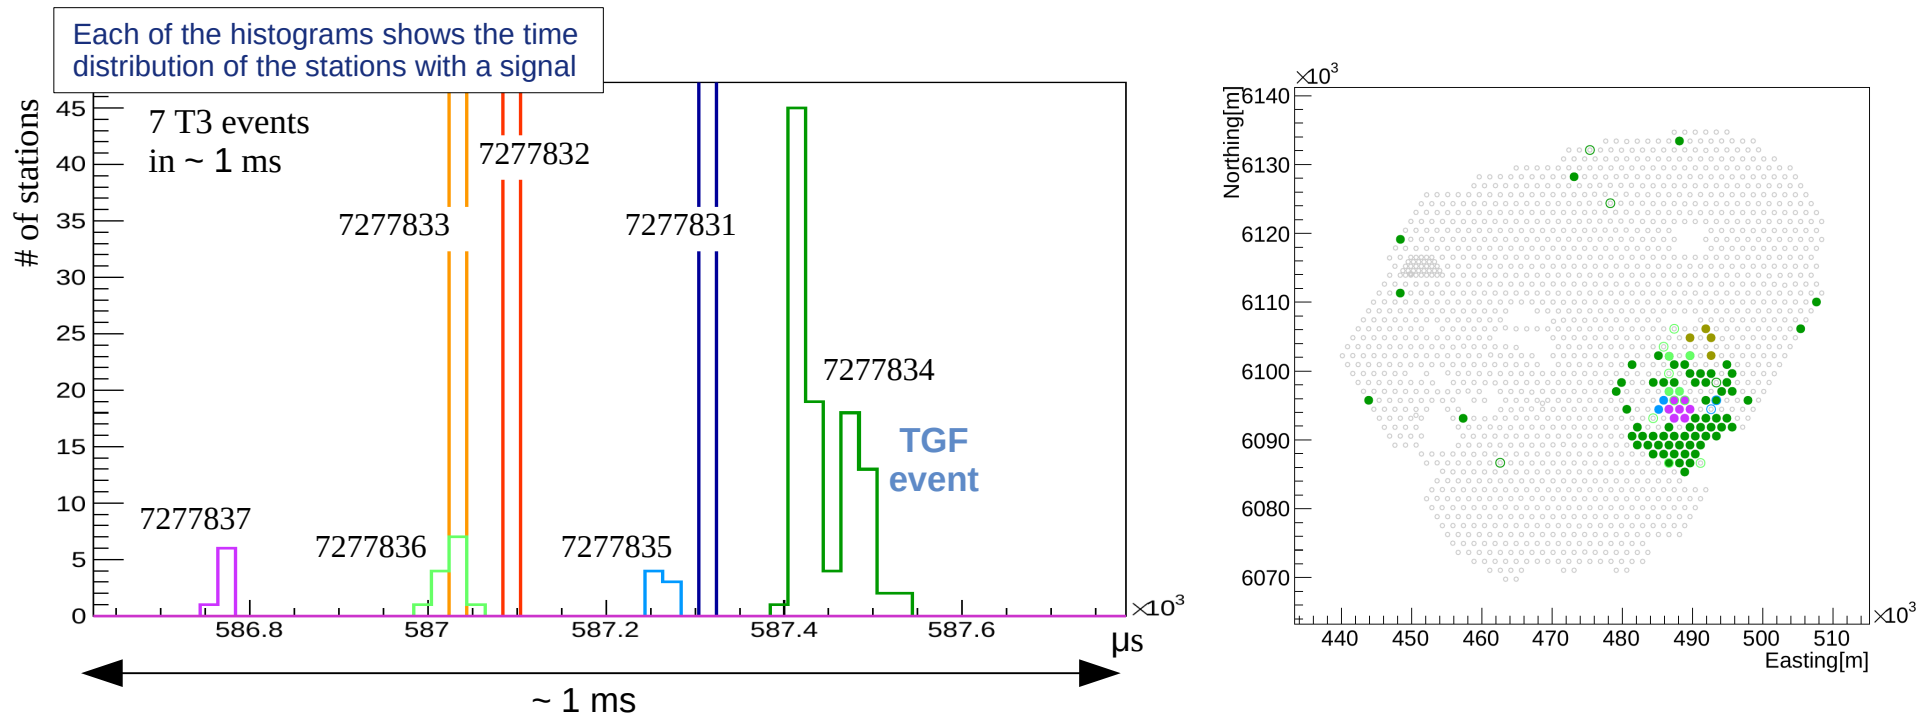

TYPE 2: TGFs produced at the upper (generally positive) end of a channel already connected to ground (-CG lightning).

TYPE 3: TGFs produced without any evidence of an existing leader / channel [1, 2] but rather through a glow instability [2], probably leading to the relativistic feedback streamer proposed by Dwyer [3].

We avoid making distinctions based on the direction of the primary TGF beam (up or down) or the detector platform (orbital, aircraft, ground, or balloon) as these distinctions don't relate directly to the physics of the phenomenon itself.

Events presented with a lavender border are results from the THOR-type detector arrays deployed by the University of California, Santa Cruz. THOR arrays include 4 detectors of intentionally varied size and material (3 plastic scintillators and one NaI scintillator) to maximize dynamic range [4].

What TGF type are we observing?

Behaviour similar to the events observed by the Santa Cruz group (J. Ortberg & D. Smith) in Japan and New Mexico: timing consistent with a stepped leader making a connection at that time \rightarrow the upward return stroke enhances the field in the right direction for the avalanche to be aimed toward the ground with a strong horizontal component (**-CG** – negative cloud-to-ground).

Detailed lightning information not available at the time of our events...hoping for new events \rightarrow see Matteo's talk

Usage: Secondary publications and information retrieval purposes.

Structure: You may use the `description` environment to structure your abstract; use the optional argument of the `\item` command to give the category of each item.

I. INTRODUCTION

Since the start of the operation of the Pierre Auger Observatory[1], very peculiar events have been observed, during stormy days, with its surface detector, an array of water-Cherenkov detectors. The Observatory, located in the Argentinian Pampa Amarilla, was designed to detect extensive air showers produced in atmosphere by interactions of cosmic rays of ultra-high energy, namely above 10^{17} eV. While the footprint of a shower gener-

Wada et al. [7], while additional five TGFs were detected in the nearby area of Uchinada [8, 9]. Downward TGFs have also been observed with the Telescope Array [10], another large cosmic-ray observatory located in Utah.

In this paper, we report on TGF observations made with the Pierre Auger Observatory: although unexpected for an instrument optimised for the detection of cosmic rays, they illustrate its additional potential for the detection and characterisation of downward TGFs. We will show how the characteristics of the surface detec-

Abstract

The Pierre Auger Observatory, a 3000 km² detector array that sits 1.4 km above sea level in Argentina, has the unique ability to map the entire footprint of Terrestrial Gamma-ray Flashes (TGFs) incident on the ground. This is in stark contrast to the vast majority of TGF detections that only occur in a single point in space. In this paper we leverage this capability to perform two novel analyses on an event from the summer of 2007. First, we triangulate the source of the TGF to 2.1 ± 0.3 km using the arrival time of the gamma rays themselves at the detector array, independently of any information regarding the lightning channel. With the source position has been established, we can analyze the spatial distribution of the TGF on the ground with respect to that center. Not only do we find that one side of the TGF shows significantly higher flux than the other, as one would expect if it were tilted with respect to its vertical axis, but we also find an asymmetric azimuthal structure consisting of two clear peaks in intensity offset by about 150° from each other. This azimuthal structure is not possible under the traditional uniform electric field model of a TGF. Thus we use Geant4 simulations to explore what possible asymmetric source regions would lead to the asymmetric footprint seen on the ground.
