

# SalSA

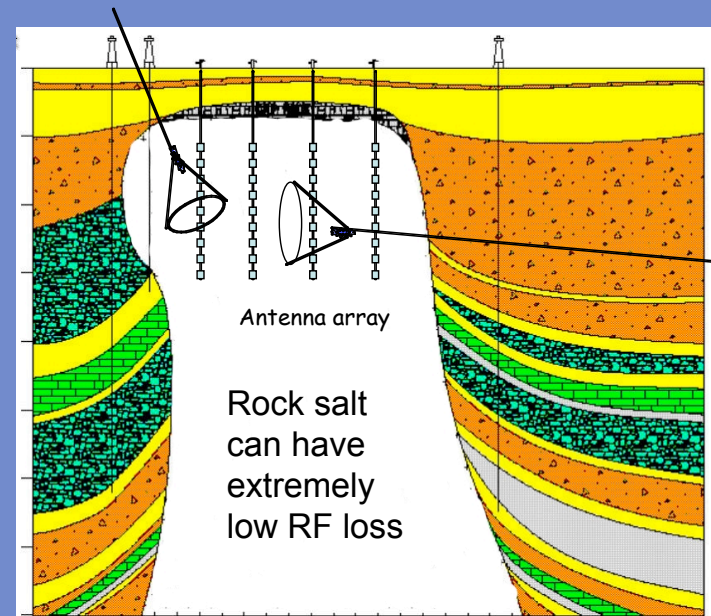

Amy Connolly (UCL)  
for the SalSA Collaboration

# Concept

- Salt formations that extend several km's wide x 10 km deep exist throughout the world
- Domes are formed from 100-200 M year old dried sea salt - diapirism

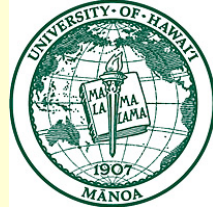

- Salt domes can be very pure
- Askaryan array in salt could be drilled from surface (expensive) or laid along floors of a salt mine

# Salt Clarity

- Before a SalSA experiment can proceed, long attenuation lengths for radio in salt need to be confirmed
  - Ideally >250 m at 200 MHz
- Ground penetrating radar (GPR) measurements point to low loss
- 1970's Stewart and Unterburger (440 MHz radar at Cote Blache Salt Mine)
  - Quote 2-3 dB/100 ft. typical for dry salt in general
    - 90-140 m field attn. lengths typical
  - One multi-reflected signal with total path length 1244 m
    - 138 m field attn. lengths *minimum*

# Previous Attenuation Length Measurements in Salt

P. Gorham, D. Saltzberg, A. Odian, D. Williams, D. Besson, G. Frichter, S. Tantawi

- Hockley mine near Houston, Texas:
  - Minimum 40 m, up to ~250 m
  - Large uncertainties due to lower power system used

# Cote Blanche Salt Mine, Louisiana, USA

A. Connolly (UCL), A. Goodhue (UCLA), C. Miki (Hawaii), R. Nichol (UCL), D. Saltzberg (UCLA), M. Cherry (LSU), J. Marsh (LSU)

- Visited Cote Blanche salt mine to measure radio attn. lengths in salt
- Same mine where GPR experts saw lowest loss in any mine visited

# Antennas

MF  
~200-  
400 MHz

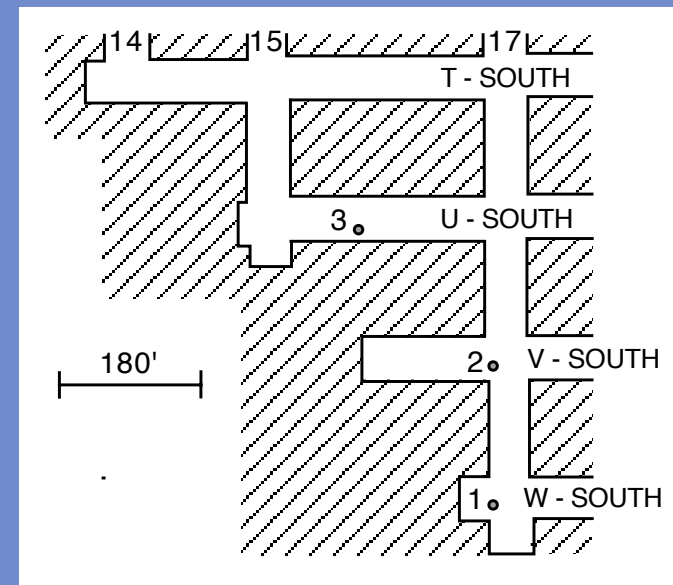

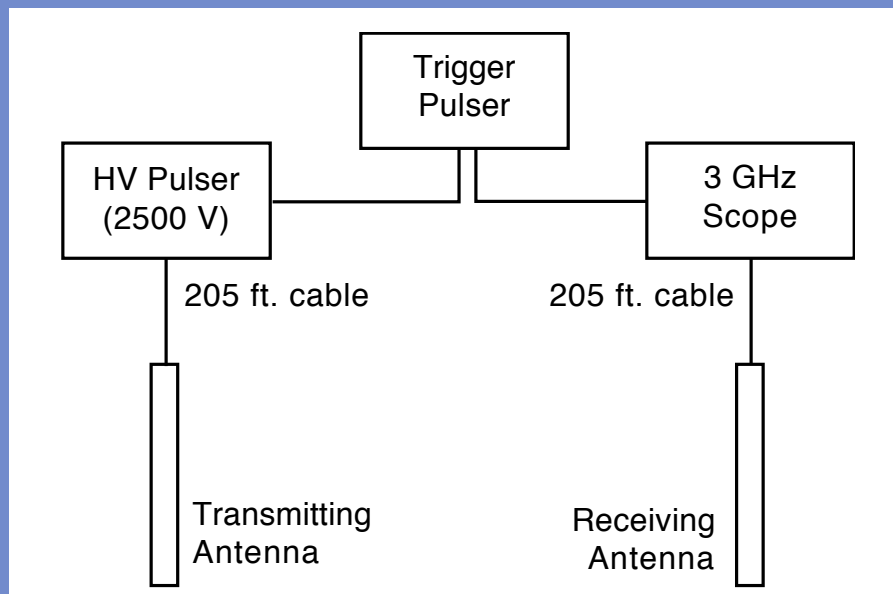

LF  
144-176 MHz

HF  
800 MHz,  
25 MHz  
BW

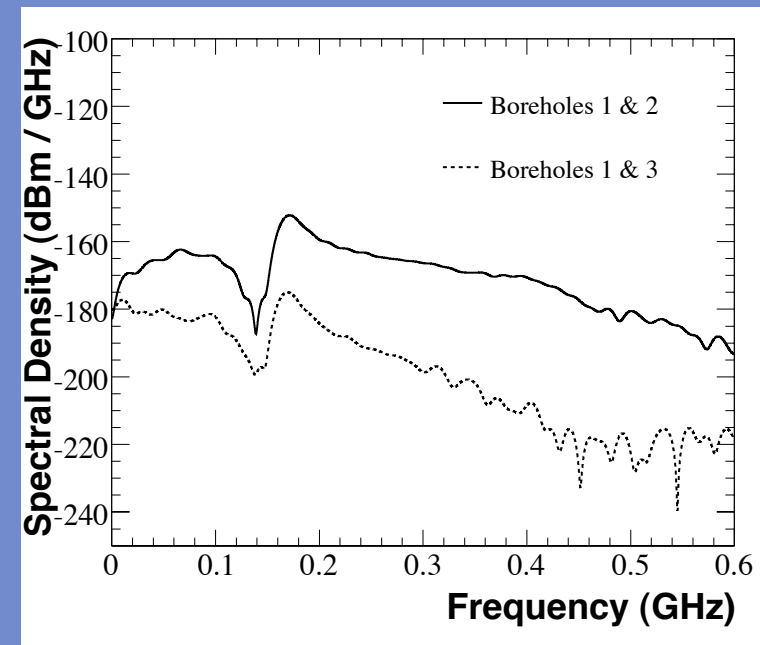

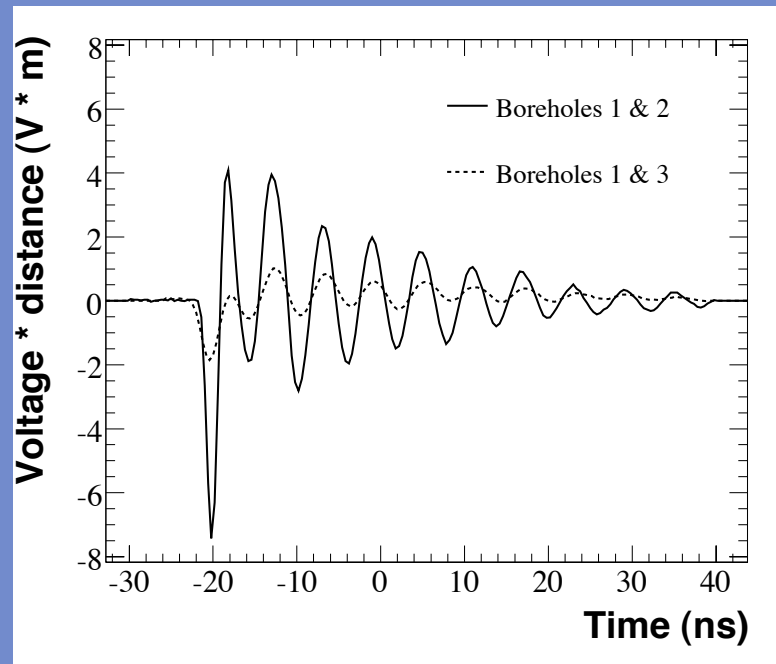

# Measurement

- Measurements made at 1500 ft. level of the mine
- Rx and Tx separated by 163 ft. and 663 ft. (168 m) distance in custom boreholes 100-200 ft. (30-60 m) deep

# Sample Waveforms

90 ft. depth  
MF antennas

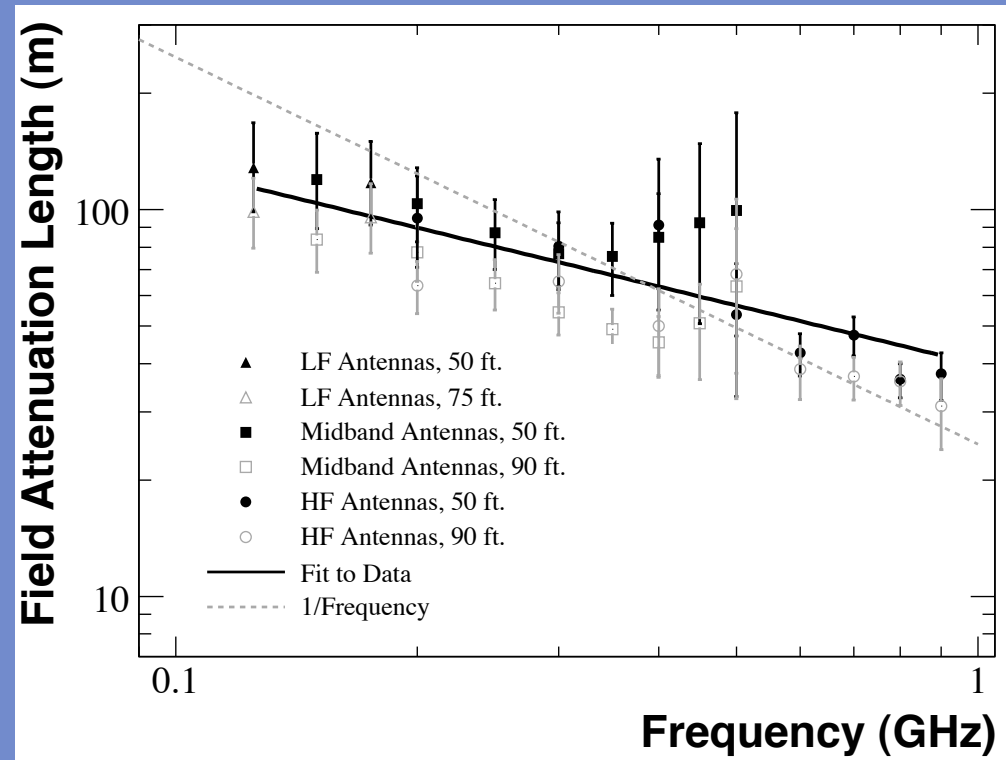

# Attenuation Lengths

Fit to 
$$L_{\alpha}(\nu) = a \cdot \left( \frac{\nu}{1 \text{ GHz}} \right)^b$$

$$b = -0.57 \pm 0.06$$

$$\chi^2 / \text{dof} = 25.6 / 36$$

- 150 MHz:  $93 \pm 7$  m
- 300 MHz:  $63 \pm 3$  m
- 800 MHz:  $36 \pm 2$  m

Recall: We estimate from Cote Blanche GPR result  
 $L_{\alpha} > 139$  m @ 440 MHz have been observed

# Simulations

- Simulate the impact of these attn. lengths on a SalSA sensitivity
- For comparison with previous estimates:
  - 10 x 10 x 10 dipole antennas
  - 150 MHz center frequency, 50% BW
  - 4 antennas hit,  $\text{SNR}=4\sigma$

Previous: 300 m at 300 MHz,  $\nu^{-1}$  dependence  
~10 GZK events / year

Compare: 63 m at 300 MHz,  $\nu^{-0.57}$  dependence  
~1 GZK event / year

# Future / Conclusions

- Before a SalSA can proceed, affordability aside, we need to definitively measure long attenuation lengths in salt ( $> \approx 250$  m)
- Borehole method works well, but only allows to sample limited region of salt per mine visit
- Would like to construct a GPR system to sample salt more efficiently
- Currently it looks difficult for salt to compete in sensitivity with any future detector in ice, but
  - It is important to explore new media
  - Salt could complement ice (Northern sky, accessibility)
